

The Impact of Urbanization on Local Ecosystems

Department of Environmental Studies · Working Paper

Abstract

Urbanization has accelerated dramatically over the past century, fundamentally altering the environments in which countless species live. This paper examines the ecological consequences of rapid urban expansion, with a particular focus on biodiversity loss and habitat fragmentation. Drawing on data collected across twelve metropolitan regions, we find consistent evidence that unmanaged growth disproportionately affects sensitive species.

Introduction

As cities continue to grow, natural habitats are increasingly replaced by concrete and asphalt. Researchers have documented a clear correlation between urban sprawl and declining pollinator populations, particularly among native bee species. This trend raises important questions about long-term ecological resilience in and around expanding urban centers.

Furthermore, the fragmentation of green spaces disrupts migratory patterns for birds and mammals alike, forcing many species to adapt or relocate entirely. In some cases, this has led to notable shifts in local biodiversity, with generalist species thriving while more specialized species struggle to survive.

Methodology

Data for this study was gathered through a combination of satellite imagery analysis and on-the-ground species counts conducted over an eighteen-month period. Each site was assessed for both the extent of urban development and the diversity of species present within a one-kilometer radius.
